The inguinal lymph nodes are an unusual site of metastases for prostate adenocarcinoma. We present a case in which a 61-y-old man with biochemically recurrent prostate cancer underwent attenuation-corrected $^{11}$C-acetate PET/CT, which demonstrated multiple foci of increased activity in the left inguinal, left iliac chain, and right inguinal regions. The attenuation-corrected CT portion of the scan also showed anterior wall thickening of the rectum. The imaging findings were suggestive of metastatic involvement of the rectum below the dentate line with subsequent spread to the inguinal lymph nodes.

Lymphatic spread of prostatic cancer rarely involves the inguinal region. In a patient presenting with inguinal lymphadenopathy, careful consideration of the routes of lymphatic drainage may allow sites of metastasis to be identified. A variety of imaging modalities have been used with variable success to identify and localize sites of recurrence.

CASE REPORT

The institutional review board approved this study, and the requirement to obtain informed consent was waived. A 61-y-old man with a history of prostate cancer (Gleason score 7) was found to have a prostate-specific antigen level of 8.0 ng/mL 20 mo after brachytherapy treatment. A radionuclide bone scan had normal findings. A subsequent CT scan of the abdomen and pelvis revealed multiple enlarged left inguinal lymph nodes, with the two largest measuring 2.3 and 2 cm and several other mildly enlarged nodes measuring less than 1 cm. On the basis of these results, the patient was then referred for an attenuation-corrected $^{11}$C-acetate scan PET/CT scan.

The scan demonstrated a focal concentration of increased metabolic activity ($S_{\text{max}}$ 3.92) in the posterior region of the prostate at the interface of the anterior wall of the rectum (Fig. 1). Associated thickening of the anterior wall of the rectum was also demonstrated on the CT portion of the scan.

Extensive hypermetabolic lymphadenopathy was noted in the left inguinal region ($S_{\text{max}}$ 2.28, 6.11, 4.51, and 5.05) (Fig. 2) and external iliac chain ($S_{\text{max}}$ 5.42, 2.28, and 3.39).
(Figs. 3 and 4), with a smaller lymph node in the right inguinal area anterior to the femoral neurovascular bundle ($\text{SUV}_{\text{max}} 1.91$).

No osseous metastases were seen. The patient declined biopsy and chose to undergo salvage therapy with intensity-modulated radiation.

**DISCUSSION**

In the anal canal, the dentate line is the landmark for two different systems of lymphatic drainage: above, to the inferior mesenteric and internal iliac nodes, and below, to the superficial inguinal nodes (1). In prostate cancer, the external and internal iliac, obturator, presacral, and paraaortic lymph nodes are most often involved in primary lymphatic spread (2). Although inguinal lymphadenopathy is rare in prostate carcinoma, involvement of the rectum below the dentate line can be the source of metastasis to inguinal lymph nodes (3,4).

Identification of the precise anatomic location of all involved lymph nodes is mandatory if salvage therapy with intensity-modulated radiation or surgery is to be considered. $^{11}$C-acetate, like $^{11}$C-choline and $^{18}$F-choline, is a radioisotope that has been shown to have a strong positive correlation on attenuation-corrected PET/CT imaging with prostate cancer metastases. Once the patient has achieved a prostate-specific antigen threshold of 1.24 ng/mL or a prostate-specific antigen doubling time of less than 6 mo, the scan achieves a putative sensitivity and specificity of 86.6% and 65.8%, respectively (5). Currently, the best application of attenuation-corrected $^{11}$C-acetate PET/CT lies in detecting prostate cancer metastasis after biochemical recurrence or in detecting extraprostatic spread before surgery.

Other metabolic imaging, such as attenuation-corrected $^{18}$F-FDG PET/CT, was not performed, as prostate cancer

cells are not particularly glucose-avid and studies have shown the superiority of attenuation-corrected $^{11}$C-acetate PET/CT (5). Similarly, although multiparametric MR imaging has shown tremendous potential in detecting locally recurrent prostate cancer, further studies are needed to elucidate its usefulness in detecting lymph node metastases.

CONCLUSION
Prostate cancer metastases to the inguinal nodes are rare. In this case, attenuation-corrected $^{11}$C-acetate PET/CT effectively demonstrated prostate cancer recurrence with inguinal node uptake, suggestive of metastatic involvement of the rectum below the dentate line.
